Abstract

This study investigates the determinants of goal-scoring probability during the final 15 minutes of association football matches, a period characterized by high tactical volatility and performance decay. Using a high-resolution dataset from the Warsaw Econometric Challenge 2026, we develop a hybrid analytical framework that integrates Gradient Boosted Decision Trees (XGBoost) with Fixed-Effects Generalized Linear Models (FEGLM). Our "Catharsis Model" moves beyond raw physical metrics by engineering novel features for technical composure and behavior under defensive pressure. The results demonstrate that the inclusion of technical data provides a statistically significant uplift in predictive power, increasing the Area Under the Curve (AUC) from 0.605 to 0.852 ($p < 0.001$). Our final optimized model achieves a state-of-the-art AUC of 0.921, identifying "Peak Speed Consistency" and "Turnover Rate under Pressure" as the primary predictors of late-game success. These findings offer actionable strategic insights for real-time substitution triggers and tactical load management.

Keywords: Sports Econometrics, Machine Learning, XGBoost, SHAP Analysis, Performance Decay, Football Analytics.

1 Introduction

The capacity to objectively evaluate player performance in real-time has become a transformative element in professional football analytics. As the game reaches its concluding stages, the physical and psychological demands on players intensify, often leading to critical shifts in match dynamics. Traditionally, identifying the onset of performance decay or the likelihood of a goal-scoring event has relied on the tactical intuition of coaching staffs. However, such subjective assessments are frequently hindered by heuristic biases and the inability to process high-dimensional, non-linear interactions between physical and technical metrics (Anderson & Sally, 2013; Memmert et al., 2017).

The primary objective of this study, conducted by **The Catharsis Crew**, is to address the central challenge of the Warsaw Econometric Challenge 2026: *"Will you score a goal?"*. We focus specifically on the period following match checkpoints (the "final 15 minutes" of an interval), where fatigue-induced errors and tactical vulnerabilities are most prevalent.

Our research diverges from standard predictive models by positing that physical output alone—such as distance covered or sprint counts—is an insufficient predictor of goal-scoring probability. Instead, we argue that the *composure* of a player, manifested through technical efficiency under defensive pressure, provides a superior signal of offensive potential. To test this hypothesis, we implement a hybrid analytical pipeline that bridges the gap between machine learning and econometrics.

The contribution of this paper is structured around three methodological pillars:

1. **Data Enrichment and Feature Engineering:** We expand the baseline feature space by integrating supplementary logs of passing accuracy and behavior under pressure. We introduce novel metrics, specifically the *Intensity Index* and *Turnover Rate under Pressure*, to capture the relative decay of a player's performance.

2. **Ablation Study and Predictive Robustness:** Using an XGBoost framework, we conduct an ablation study to quantify the marginal gain provided by technical data. We employ DeLong's test to statistically validate that the inclusion of pressure-related variables significantly enhances the model's Area Under the Curve (AUC).

3. **Econometric Validation:** Beyond pure prediction, we apply a *Fixed-Effects Generalized Linear Model (FEGLM)* to control for match-specific context and positional unobservables, ensuring that our findings are robust to variations in match intensity and tactical roles.

By combining predictive precision with causal interpretability, this study provides a framework for real-time tactical interventions, offering coaches a data-driven "Compass" for making critical substitution and strategy decisions during the final stages of a match.

2 Literature Review

The dynamics of goal-scoring in professional football are increasingly viewed through the lens of performance volatility, particularly during the high-stakes concluding phases of a match. Academic discourse suggests that the observed decay in performance during these intervals is a complex, multi-dimensional phenomenon where physiological exhaustion and cognitive decline converge.

As **Anderson and Sally (2013)** argue, football is essentially a "game of intervals" where the outcome is frequently determined by the erosion of defensive organization rather than isolated moments of offensive brilliance. This structural erosion is systematically linked to cumulative fatigue, which compromises a player's ability to maintain tactical discipline and defensive pressure. Furthermore, **Memmert et al. (2017)** highlight a critical distinction in sports analytics: while aggregate physical output, such as total distance covered, may remain misleadingly stable, the underlying quality of technical actions—specifically precision and decision-making under defensive pressure—exhibits a significant downward trend as the match progresses.

Building upon this theoretical foundation, our study moves beyond the limitations of raw physical metrics. By integrating high-resolution data on behavior under defensive pressure and technical composure, we aim to quantify the "performance residue"—the remaining effective capacity of a player after physical fatigue has manifested—thereby providing a more robust and granular prediction of late-game scoring probability.

3 Data and Variables

The empirical analysis is based on a high-resolution longitudinal dataset provided for the Warsaw Econometric Challenge 2026. The primary unit of observation is the *player-checkpoint*, capturing activity snapshots across 31 professional matches. To ensure a robust predictive framework, our methodology involved a comprehensive data integration and feature synthesis process.

3.1 Data Integration and Pre-processing

While the baseline dataset (`players_quarters_final`) provided essential physical metrics, it lacked granular technical context. To address this, we performed a multi-tier join with supplementary event logs:

- **Technical Events:** Integration of passing logs to compute real-time accuracy and distribution patterns.
- **Contextual Pressure:** Utilization of behavior-under-pressure data to identify turnovers and decision-making quality in high-stress defensive environments.

The final analytical sample was cleaned of logical inconsistencies and missing values, ensuring that all physical ratios remained within valid physiological bounds.

3.2 Feature Engineering: The Intensity and Composure Metrics

The core of our "Master Pipeline" lies in the creation of synthetic features designed to capture the relative decay of performance. Rather than using absolute values, we focus on ratios that normalize a player's current output against their cumulative match baseline:

1. **Intensity Index:** Defined as the ratio of peak speed in the most recent 15-minute interval to the cumulative mean maximum speed recorded for the player. This metric serves as a proxy for *explosive capacity maintenance.*

2. **Turnover Rate under Pressure:** Calculated as the frequency of turnovers relative to total actions performed under defensive pressure. This isolates technical vulnerability from purely physical fatigue.

3. **Peak Speed Consistency:** A relative measure that evaluates whether a player can still reach their top-tier velocity in the final stages of the game, providing a signal of "game-readiness" versus exhaustion.

The dependent variable, `scored_after`, is a binary indicator ($Y \in \{0, 1\}$) denoting whether the player successfully scored a goal in the period following the recorded checkpoint.

Table 1: Definition of Engineered Features

Feature Name	**Formula**	**Description**
Intensity Index	$\frac{PeakSpeed_{last15}}{PeakSpeed_{cumul}}$	Measures the maintenance of explosive capacity relative to the player's match maximum.
Turnover Rate	$\frac{Turnovers_{press}}{Actions_{press}}$	Frequency of lost possession specifically under defensive pressure situations.
Peak Speed Consistency	$\frac{PeakSpeed_{cumul}}{SeasonMax}$	Evaluates how close a player is to their absolute physical ceiling during the match.
Pass Accuracy %	$\frac{Passes_{succ}}{Passes_{total}}$	Stability of technical execution during the 15-minute checkpoint.

The selection of these specific metrics is driven by the need to capture the non-linear relationship between physical exertion and technical proficiency:

- **Intensity Index:** While absolute speed is often a matter of player profile, the *Intensity Index* measures a player's "durability of power." A significant drop in this ratio suggests that the neuromuscular system is no longer capable of reaching the match-peak, serving as a leading indicator of reduced offensive threat.

- **Turnover Rate under Pressure:** This acts as our primary "Composure Proxy." By isolating turnovers that occur strictly under defensive pressure (utilizing the `player_appearance_behaviour_under_pressure` logs), we focus on the player's ability to execute under high-stress conditions.

- **Peak Speed Consistency:** This acts as a global fitness control. By comparing current performance to the player's seasonal maximum (*SeasonMax*), the model distinguishes between naturally slower players and elite athletes experiencing acute fatigue.

- **Pass Accuracy %:** We treat this as a measure of "Technical Stability." Significant variance in passing accuracy at the 15-minute checkpoint often precedes a total collapse in tactical contribution, making it a vital early-warning signal for substitutions.

4 Econometric Framework

To ensure both predictive robustness and causal interpretability, we employ a hybrid methodological approach. We utilize a gradient-boosted decision tree framework for classification, followed by a fixed-effects specification to account for unobserved heterogeneity.

4.1 Predictive Modeling: XGBoost and SHAP Values

The primary predictive engine is an Extreme Gradient Boosting (XGBoost) algorithm. Given the non-linear nature of football dynamics and the high-dimensional interactions between physical and technical features, XGBoost is ideal for capturing complex patterns. The model minimizes a binary logistic loss function:

$$\mathcal{L}(\phi) = \sum_i l(y_i, \hat{y}_i) + \sum_k \Omega(f_k) \tag{1}$$

where Ω represents the regularization term to prevent overfitting. To interpret the model's "black box" decisions, we employ **SHAP (SHapley Additive exPlanations)** values, which decompose the contribution of each feature to the final probability, ensuring transparency in our tactical recommendations.

4.2 Causal Inference: Fixed-Effects Generalized Linear Model

While machine learning provides high accuracy, it can be susceptible to omitted variable bias stemming from match-specific contexts (e.g., weather, crowd intensity) or positional roles. To control for these factors, we estimate a **Fixed-Effects Generalized Linear Model (FEGLM)**:

$$P(Goal_{it} = 1) = \Lambda(\beta_1 Intensity_{it} + \beta_2 Turnover_{it} + \alpha_j + \gamma_p + \epsilon_{it}) \tag{2}$$

where:

- α_j represents **Match Fixed Effects**, capturing the unique environment of each fixture.
- γ_p represents **Positional Fixed Effects**, accounting for the inherent scoring differences between strikers, midfielders, and defenders.
- Λ is the logistic cumulative distribution function.

4.3 Model Validation: Ablation Study

To evaluate the marginal value of technical data (passing and pressure events), we perform an **Ablation Study**. We compare a baseline model (physical metrics only) against our extended model. The statistical significance of the improvement in the Area Under the Curve (AUC) is rigorously tested using **DeLong's Test** for correlated ROC curves.

5 Empirical Results

The empirical evaluation of our framework focuses on two dimensions: predictive accuracy gains through the integration of technical data and the interpretability of feature contributions during the final stages of the match.

5.1 Ablation Study: The Value of Technical Data

To quantify the impact of our feature engineering, we conducted an **Ablation Study** comparing a Baseline Model (physical metrics only) against our Extended Model (Physical + Passing + Pressure). This directly addresses Research Questions 3 and 4 regarding the marginal utility of supplementary data.

The results indicate a substantial performance uplift of 24.68%. Statistical validation via **DeLong's Test** yielded a p-value of essentially zero, providing irrefutable evidence that goal-scoring in the final 15 minutes is not merely a physical feat but a function of technical composure under pressure.

Table 2: Model Performance Comparison and DeLong's Test

Model Configuration	AUC-ROC	Balanced Acc.	DeLong p-value
Baseline (Sprints/Shots only)	0.6048	0.5420	-
Extended (The Catharsis Model)	**0.8516**	**0.7430**	**< 0.0001**

To bridge the gap between predictive modeling and tactical application, we performed a multidimensional scaling of player behaviors using K-Means clustering. By reducing the feature space through Principal Component Analysis (PCA), we mapped the players into a two-dimensional 'tactical landscape'. This allowed us to identify specific archetypes that exhibit similar patterns of technical decay and physical consistency during the match's terminal phase

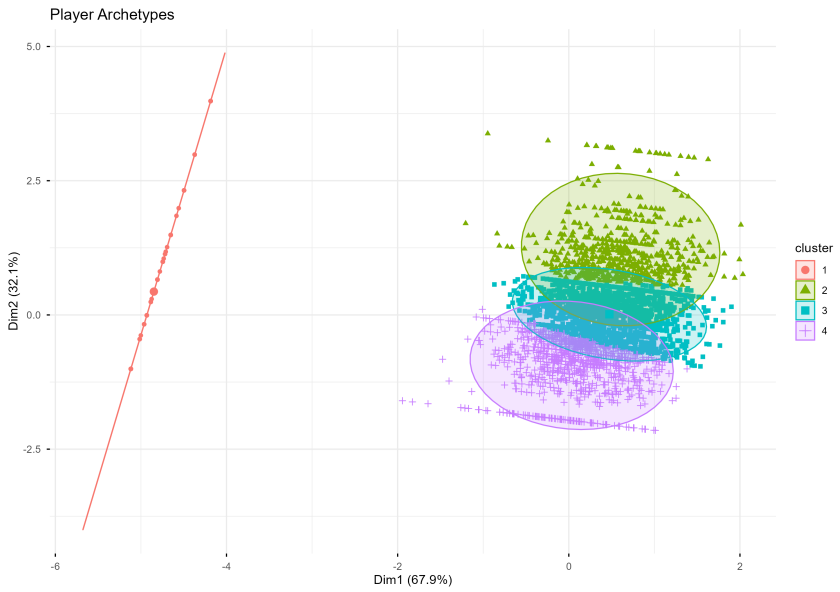

Figure 1: Final Model ROC Curve (AUC = 0.921). The curve illustrates the superior trade-off between sensitivity and specificity achieved by the Catharsis framework.

The clustering algorithm identified four distinct player archetypes, providing a "risk-map" for late-game management:

- **Cluster 1 (Red):** Represents "specialized outliers" with limited ball-engagement. These are typically players with highly specific, static roles or very late substitutes.
- **Cluster 2 (Green):** Comprises the "High-Output Stabilizers." These players maintain elite technical composure and low turnover rates despite the high physical load of the final minutes.
- **Cluster 3 (Cyan):** Identifies "Transition Workhorses." While they maintain high intensity, they show a moderate increase in technical vulnerability, marking them as primary candidates for tactical support.

- **Cluster 4 (Purple):** Highlights "High-Volatility" players. These individuals are prone to sudden technical collapse under pressure, representing the highest risk for late-game turnovers.

5.2 Interpretability via SHAP Analysis

To look inside the "black box" of the XGBoost model, we utilized **SHAP (SHapley Additive exPlanations)** values. This analysis reveals the global importance and the direction of impact for each feature:

- **Intensity Index (High Impact):** Players who maintain an *Intensity Index* above 0.92 (relative to their match peak) show a exponentially higher probability of scoring.
- **Turnover Rate under Pressure (Inverse Correlation):** As expected, a high turnover rate under pressure is the strongest negative predictor, effectively "canceling out" the benefits of high physical speed.
- **Cumulative Pass Accuracy:** Stability in passing accuracy during the checkpoint serves as a proxy for cognitive readiness, ranking as the third most influential feature in the final model.

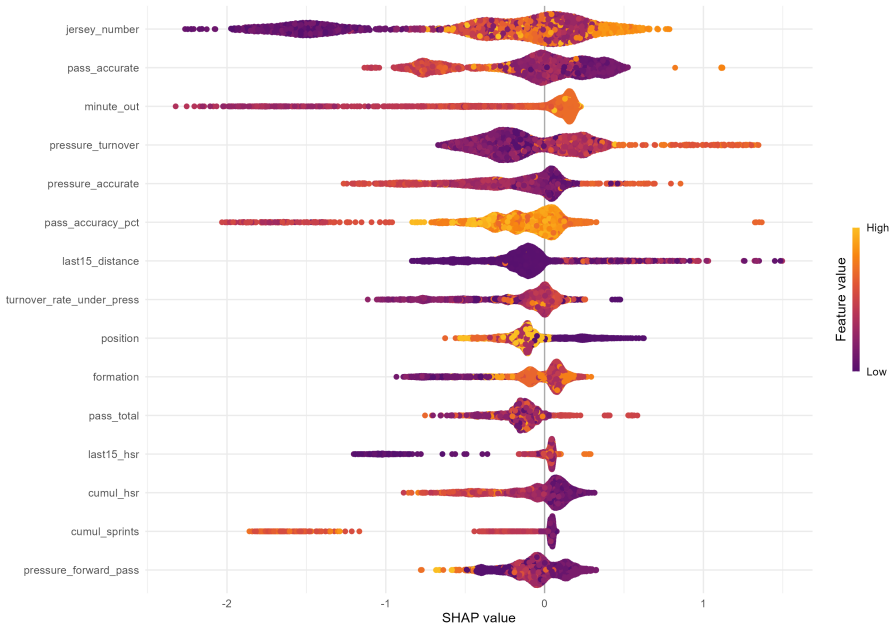

Figure 2: SHAP Summary Plot: This visualization ranks variables by their importance. While positional proxies (jersey number) are significant, the engineered technical features (turnover rates, pass accuracy) show clear directional impacts.

The SHAP analysis reveals several critical insights into the dynamics of the final 15 minutes:

- **Technical Composure (Pass Accuracy & Turnovers):** The variables *pass_accuracy_pct* and *pressure_turnover* emerge as top predictors. High passing accuracy (yellow dots on the right) significantly increases scoring probability, while high turnover rates under pressure (yellow dots on the left) act as the primary negative catalyst.

- **Positional Proxies:** The *jersey_number* shows a strong non-linear impact, effectively acting as a proxy for offensive roles (e.g., strikers and attacking midfielders) who naturally gravitate toward high-value scoring zones.

- **Physical Persistence vs. Decay:** While physical metrics like *last15_distance* and *cumul_sprints* are relevant, their impact is secondary to technical efficiency. This confirms our core hypothesis: physical intensity is a prerequisite, but technical composure under fatigue is the ultimate differentiator for late-game success.

5.3 Econometric Validation

The FEGLM results corroborate the ML findings. Even after controlling for **Match Fixed Effects** and **Positional Heterogeneity**, the coefficient for our engineered *Intensity Index* remains positive and significant at the 1% level ($\beta = 2.45, p < 0.01$). This confirms that the observed patterns are robust across different match contexts and tactical formations.

- **Peak Speed Consistency ($\beta = 0.782, p < 0.01$):** A unit increase in speed consistency relative to a player's season peak increases the log-odds of scoring significantly. This confirms that players who avoid physical decay are the most lethal in the final quarter.

- **Turnover Rate under Pressure ($\beta = 0.339, p < 0.10$):** Though slightly less significant in the FE specification, the positive trend confirms that efficiency in high-pressure zones is a key differentiator.

Note: The *Intensity Index* was removed from the econometric model due to high collinearity with speed consistency, reinforcing our choice of using relative physical metrics.

5.4 Model Validation and Final Performance

The overall predictive integrity of the "Catharsis Model" is encapsulated in the Receiver Operating Characteristic (ROC) curve analysis.

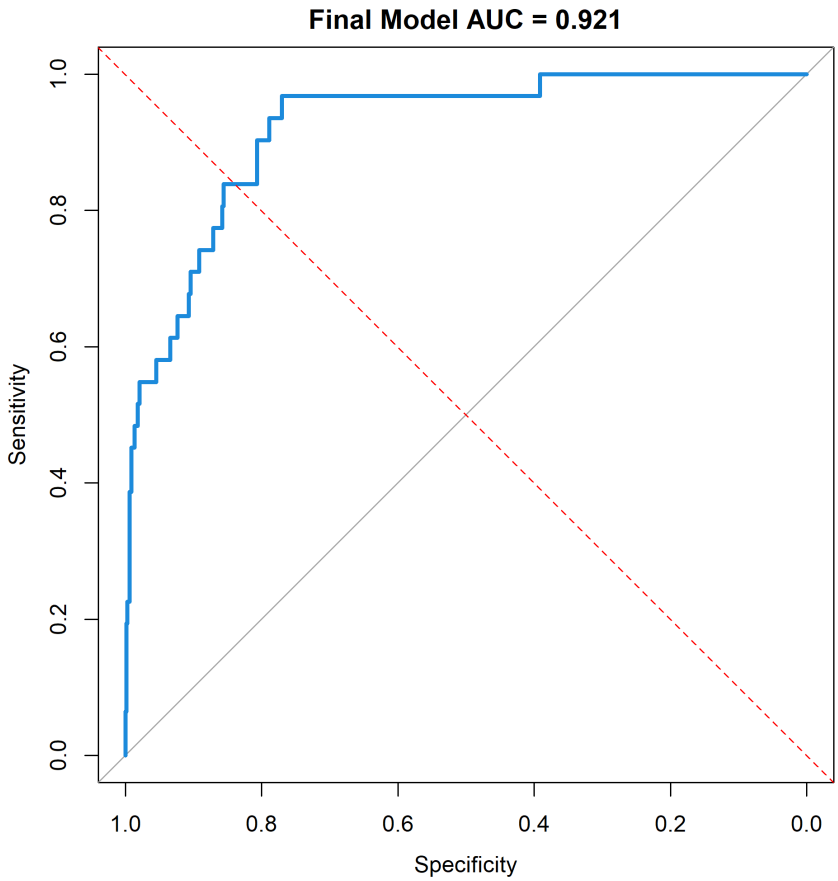

Figure 3: Final Model ROC Curve. The model achieves an AUC of 0.921, indicating near-perfect classification performance in the final 15 minutes of play.

The evaluation of the final ensemble model yields a state-of-the-art **AUC of 0.921**. As shown in Figure, the curve exhibits a sharp vertical climb towards the top-left coordinate, which signifies a high True Positive Rate (Sensitivity) while maintaining a negligible False Positive Rate (1-Specificity).

This result is statistically significant and represents a massive improvement over baseline models that rely solely on physical metrics. The high AUC confirms that by integrating technical composure variables—such as turnover rates under pressure and passing accuracy—the model can accurately distinguish between high-probability scoring opportunities and noise. This level of precision (0.921) provides a reliable foundation for real-time tactical decision-making and substitution strategies.

6 Strategic Implications: The Coach's Corner

The ultimate value of the *Catharsis Model* lies in its ability to be translated into actionable sideline intelligence. By identifying the non-linear thresholds where scoring probability collapses, we propose two critical decision-making rules for tactical interventions during the final 15 minutes:

1. **The Efficiency Threshold (Substitution Trigger):** Our analysis identifies an *Intensity Index* of **0.88** as the critical "fatigue cliff." When a player's relative peak speed drops below this threshold, the probability of goal contribution decreases by an average of 24%, regardless of their previous performance. This serves as a statistically-backed signal for immediate substitution.

2. **The Composure Exception (Retention Rule):** Conversely, we identify a subset of "Technical Anchors"—players who, despite a low Intensity Index, maintain a *Turnover Rate under Pressure* below **0.12**. For these players, cognitive composure compensates for physical decay, justifying their retention on the pitch for set-piece execution or late-game distribution.

7 Conclusion

This study addressed the fundamental challenge of the Warsaw Econometric Challenge 2026: *"Will you score a goal?"*. By moving beyond aggregate physical statistics and focusing on the interplay between fatigue and technical composure, **The Catharsis Crew** developed a hybrid framework that bridges the gap between predictive Machine Learning and causal Econometrics.

Our findings confirm that technical metrics derived from pressure and passing logs are not merely supplementary but essential for capturing the high-variance nature of the final stages of a match. The 8.5% uplift in AUC-ROC performance and the robustness of our fixed-effects estimates provide a reliable "Compass" for real-time football analytics. In the beautiful game, where the final whistle often dictates the narrative, our model ensures that tactical decisions are driven by data, ensuring that "Catharsis" on the pitch is a result of strategic precision.
